Bounded evaluation using views is to compute the answers \( Q(D) \) to a query \( Q \) in a dataset \( D \) by accessing only cached views and a small fraction \( D_Q \) of \( D \) such that the size \( |D_Q| \) of \( D_Q \) and the time to identify \( D_Q \) are independent of \( |D| \), no matter how big \( D \) is. Though proven effective for relational data, it has yet been investigated for graph data. In light of this, we study the problem of bounded pattern matching using views. We first introduce access schema \( C \) for graphs and propose a notion of joint containment to characterize bounded pattern matching using views. We show that a pattern query \( Q \) can be boundedly evaluated using views \( V(G) \) and a fraction \( G_Q \) of \( G \) if and only if the query \( Q \) is jointly contained by \( V \) and \( C \). Based on the characterization, we develop an efficient algorithm as well as an optimization strategy to compute matches by using \( V(G) \) and \( G_Q \). Using real-life and synthetic data, we experimentally verify the performance of these algorithms, and show that (a) our algorithm for joint containment determination is not only effective but also efficient; and (b) our matching algorithm significantly outperforms its counterpart, and the optimization technique can further improve performance by eliminating unnecessary input.

**Keywords:** Bounded evaluation; Graph pattern matching; Views

1. Introduction

With the advent of massive scale data, it is very urgent to have effective methods for query evaluation on large scale data. One typical solution is by means of scale independence [6, 7], whose idea is to compute the answers \( Q(D) \) to a query \( Q \) in a dataset \( D \) by accessing a small fraction \( D_Q \) of \( D \) with bounded size, no matter how big the underlying \( D \) is. Following the idea, [11, 12] show that nontrivial queries can be scale independent under a set \( C \) of access constraints, a form of cardinality constraints with associated indices, and refer to a query \( Q \) as boundedly evaluable if for all datasets \( D \) that satisfy \( C \), \( Q(D) \) can be evaluated from a fraction \( D_Q \) of \( D \), and the time for
identifying and fetching $D_Q$ and the size $|D_Q|$ of $D_Q$ are independent of $|D|$. Still, many queries are not boundedly evaluable, hence bounded evaluation with views was proposed by [8], which is to select and materialize a set $V$ of small views, and answer $Q$ on $D$ by using cached views $V(D)$ and an additional small fraction $D_Q$ of $D$. Then, the queries that are not boundedly evaluable can be efficiently answered with views and a small fraction of original data with bounded size.

Bounded evaluation with views have proven effective for querying relational data [9], but the need for studying the problem is even more evident for graph pattern matching (GPM), since (a) GPM has been widely used in social analysis [27] which is becoming increasingly important nowadays; (b) it is a challenging task to perform graph pattern matching on real-life graphs due to their sheer size; and (c) view-based matching technique is often too restrictive. Fortunately, bounded pattern matching using views fills this critical void. Indeed, cardinality constraints are imposed by social graphs, e.g., on LinkedIn, a person can have at most 30000 connections and most of people have friends less than 1000 [2]; on Facebook, a person can have no more than 5000 friends [5], etc. Given the constraints and a set of well-chosen views $V$ along with their caches $V(G)$ on graphs $G$, GPM can be evaluated by using the views plus a small fraction $G_Q$ of $G$ of bounded size, no matter how large $G$ is.

**Example:** A fraction of a recommendation network $G$ is shown in Fig. 1(a), where each node denotes a person with job title (e.g., project manager (PM), business analyst (BA), database administrator (DBA), programmer (PRG), user interface designer (UI) and software tester (ST)); and each edge indicates collaboration, e.g., $(PM_1, PRG_1)$ indicates that PRG_1 worked well with PM_1 on a project led by PM_1.

To build a team for software development, one issues a pattern query $Q$ depicted in Fig. 1(b). The team members need to satisfy the following requirements: (1) with expertise: PM, BA, DBA, PRG, UI and ST; (2) meeting the following collaborative experience: (i) BA, PRG and DBA worked well under the project manager PM; and (ii) DBA, ST and UI have been supervised by PRG, and collaborated well with PRG. It is then a daunting task to perform graph pattern matching since it takes $O(|G|!|G|)$ time to identify all the isomorphic matches of $Q$ in $G$ [10], where $|G| = |V| + |E|$ indicates the size of $G$.

While one can do better by bounded pattern matching using views. Suppose that (1) a set of views $\mathcal{V} = \{V_1, V_2\}$ is defined and cached ($V(G) = \{V_1(G), V_2(G)\}$) as shown in Fig. 1(c), and (2) there exists an access constraint $\varphi = \langle Q_L(P_R, Q_R), N_0 \rangle$ (Fig. 1(d)) that $G$ satisfies. Here $\varphi$ states that for each DBA that has been supervised by a PM, he can be supervised by at most $N_0$ distinct PRG. One may associate $\varphi$ with an index $I_\varphi$ for fast access. As will be seen shortly, with index $I_\varphi$, a fraction $G_Q$ of $G$ of bounded size can be efficiently constructed, and $Q(G)$ can be answered by using $V(G)$ and $G_Q$. Since $V(G)$ already contains partial answers to $Q$ in $G$, and $V(G)$ and $G_Q$ are often much smaller than $G$, thus the cost for computing $Q(G)$ can be substantially reduced. \hfill $\Box$

This example suggests that we perform pattern matching by using views $V$, $V(G)$ and a fraction

$G_D$ of original graph $G$ of bounded size. In doing so, two key issues have to be settled. (1) How to decide whether a pattern query $Q$ is \textit{boundedly evaluable with views}? (2) How to efficiently compute $Q(G)$ with $V(G)$ and $G_Q$?

**Contributions.** This paper investigates the aforementioned questions for \textit{bounded pattern matching using views}. We focus on graph pattern matching with \textit{subgraph isomorphism} [10].

(1) We introduce \textit{access schema} defined on graph data (Section), and propose a notion of \textit{joint containment} (Section) for determining whether a pattern query is \textit{boundedly evaluable with views}. Given a pattern query $Q$, a set of views $V$ and access schema $C$ with indexes associated, we show that $Q$ is \textit{boundedly evaluable with views} if and only if $Q$ is \textit{jointly contained} by $V$ and $C$.

(2) We provide an algorithm, that works in $O(||V|| + ||C|||Q||)Q)$ time to determine \textit{joint containment}, where $||V||$ and $||C||$ refer to the cardinality of $V$ and $C$, respectively, and $|Q|$ indicates the size of $Q$. As the cost of the algorithm is dominated by $||V||$, $||C||$ and $|Q|$, which are often small in practice, the algorithm hence performs very efficiently.

(3) Based on \textit{joint containment}, we develop an algorithm to evaluate graph pattern matching by using $V(G)$ and $G_Q$ (Section). Given a pattern query $Q$, a set of views $V$ and its extension $V(G)$ on a graph $G$, and an access schema $C$ that $G$ satisfies, the algorithm computes $Q(G)$ in $O(||V|||Q||V(G)||)^{||V||}|Q||Q||C||)$ time, \textit{without accessing} $G$ at all, when $Q$ is \textit{jointly contained} in $V$ and $C$. It is far less costly than the algorithm [10] that takes $O(|G||G||)$ time to evaluate $Q$ directly on $G$, since $|Q|$, $|V|$, $||V||$, $||C||$ are very small, and $|V(G)|$ is typically \textit{much smaller} than $|G|$ in practice. We also study the \textit{minimum containment problem}, which is to find a pair of subsets $\langle V', C' \rangle$ of $V$ and $C$ such that $Q$ is jointly contained by $\langle V', C' \rangle$; and moreover, the input used by the matching algorithm can be dramatically reduced.

(4) Using real-life and synthetic graphs, we experimentally verify the performances of our algorithms (Section). We find that (a) our algorithm for joint containment checking is very efficient, \textit{e.g.}, taking only 145.5 milliseconds to determine whether a pattern query is contained by a set of views; (b) our view-based matching algorithm is efficient: it is 9.7 times faster than conventional method on \textit{Youtube} [4] with 1.6 million nodes and 4.5 million edges; (c) our optimization technique is effective: it can reduce the size of input, \textit{i.e.}, $|V(G)|$ and $|G_Q|$ by 75% and improve the efficiency by 143%, on average, over real-life graphs; and (d) our matching algorithm scales well with the data size.

In a summary of the scientific contributions, this work gives a full treatment for \textit{bounded pattern matching using views}, for pattern queries defined in terms of subgraph isomorphism. It introduces methods to efficiently determine whether a pattern query can be \textit{boundedly evaluable with views}; provides effective techniques to evaluate pattern matching using $V(G)$ and $G_Q$ which is of bounded size. In contrast with prior works, this work fills one critical void for evaluating graph pattern matching on big graphs, and yields a promising approach to querying “big” social data.

This paper is an extended version of our prior work [26]. Compared with [26], we have made following extensions. (1) We have provided proofs for Theorem 1.2, 4 and Proposition. (2) We have enriched correctness and complexity analysis for Algorithm JCont and BMatch. (3) We have provided algorithm Minimum, enriched its analysis along with a running example. (4) We have also included a few remarks and the summary for experiments for better elaboration.
Related work. We next categorize related work as follows.

Query answering using views. Answering queries using views has been well studied for relational data (see [16, 20] for surveys), XML data [15, 22, 24], and [14]. This work differs from them in the following aspects: (i) we adopt subgraph isomorphism as the semantic of pattern matching, instead of graph simulation [18] and bounded simulation [13], that are applied by [14]; (ii) we study a more practical problem to answer graph pattern matching using available views and a small fraction of graph $G$ with bounded size; and (iii) we also investigate the problem of view selection, and provide effective technique for this problem.

Scale independence. The idea of scale independence, i.e., querying dataset $D$ by accessing only a bounded amount of data in $D$, is proposed by [6–8]. Extending the idea with access schema, [11, 12] introduced bounded evaluation. To cope with nontrivial queries, [8] proposed bounded evaluation with views, i.e., evaluating queries that are not boundedly evaluable on a dataset $D$ by accessing not only cached views $\mathcal{V}(D)$ but also a small fraction of $D$ with bounded size. Furthermore, [9] explored fundamental problems of bounded evaluation with views. This work differs from [8, 9] in that the query semantics are different, and we not only conduct static analysis for fundamental problems, but also provide effective technique for matching evaluation.

Organization. The remainder of the paper is organized as follows. Section reviews the notions of data graphs, pattern queries, graph pattern matching, and views, graph pattern matching using views. Section introduces pattern containment problem and provides algorithm for pattern containment checking. Section provides view based matching algorithm, and optimization techniques to further improve matching evaluation. Extensive experimental studies are conducted in Section . Section summarizes the main results of the paper and identifies open issues.

2. Preliminaries

In this section, we first review data graphs, pattern queries and graph pattern matching. We then introduce the problem of bounded pattern matching using views.

2.1. Basic Definitions

We start with basic notations, i.e., data graphs, pattern queries and graph pattern matching.

Data graphs. A data graph is a node-labeled, directed graph $G = (V, E, L)$, where (1) $V$ is a finite set of data nodes; (2) $E \subseteq V \times V$, where $(v, v') \in E$ denotes a directed edge from node $v$ to $v'$; and (3) $L(\cdot)$ is a function such that for each node $v$ in $V$, $L(v)$ is a label from an alphabet $\Sigma$. Intuitively, $L(\cdot)$ specifies e.g., job titles, social roles, ratings, etc [19].

Pattern queries. A pattern query (or shortened as pattern) is a directed graph $Q = (V_p, E_p, f_v)$, where (1) $V_p$ is the set of pattern nodes, (2) $E_p$ is the set of pattern edges, and (3) $f_v(\cdot)$ is a function defined on $V_p$ such that for each node $u \in V_p$, $f_v(u)$ is a label in $\Sigma$.

Subgraphs & Sub-patterns. A graph $G_s = (V_s, E_s, L_s)$ is a subgraph of $G = (V, E, L)$, denoted by $G_s \subseteq G$, if $V_s \subseteq V$, $E_s \subseteq E$, and moreover, for each $v \in V_s$, $L_s(v) = L(v)$. Similarly, a pattern $Q_s = (V_p, E_p, f_v)$ is subsumed by another pattern $Q = (V_p, E_p, f_v)$, denoted by $Q_s \subseteq Q$, if $Q_s$ is a subgraph of $Q$, i.e., $V_p \subseteq V_p$, $E_p \subseteq E_p$ and for each $u \in V_p$, $f_v(u) = f_v(u)$. We say $Q_s$ a sub-pattern of $Q$ when $Q_s \subseteq Q$. 

Graph pattern matching [10]. A match of \( Q \) in \( G \) via subgraph isomorphism is a subgraph \( G_s \) of \( G \) that is isomorphic to \( Q \), i.e., there exists a bijective function \( h \) from \( V_p \) to the node set \( V_s \) of \( G_s \) such that (1) for each node \( u \in V_p \), \( f_u(u) = L(h(u)) (h(u) \in V_s) \); and (2) \( (u, u') \) is an edge in \( Q \) if and only if \( (h(u), h(u')) \) is an edge in \( G_s \).

We also use the following notations. (1) The match result of \( Q \) in \( G \), denoted as \( Q(G) \), is a set consisting of all the matches of \( Q \) in \( G \). (2) For a pattern edge \( e = (u, u') \), we derive a set \( S(e) \) from \( Q(G) \) by letting \( S(e) = \{(v, v') | v = h(u), v' = h(u'), h \in Q(G), (v, v') \in E\} \), and denote \( S(e) \) as the match set of \( e \). (3) We use \( G \sim G_s \) to denote that \( G_s \) is a match of \( Q \). (4) We denote \( |V_p| + |E_p| \) as the size \( |Q| \) of \( Q \) and \( |V| + |E| \) as the size \( |G| \) of \( G \).

2.2. Problem Formulation

We next formulate the problem of bounded pattern matching using views. We start from notions of views and view extensions, followed by access schema and problem statement.

Views. A view (a.k.a. view definition) \( V \) is also a pattern query. Its match result \( V(G) \) in a data graph \( G \) is denoted as view extension, or extension when it is clear from the context [17]. As shown in Fig. 1(c), a set of views \( \mathcal{V} = \{V_1, V_2\} \) are defined, with extensions \( V(G) = \{V_1(G), V_2(G)\} \) on \( G \) cached.

Access schema. Extended from [9], we define access schema on graphs as follows. An access schema \( \mathcal{C} \) is defined as a set of access constraints \( \phi = \langle Q_\phi(Q_L \rightarrow Q_R), N \rangle \), where \( Q_\phi \) is a pattern query, \( Q_L \) and \( Q_R \) are sub-patterns of \( Q_\phi \) such that the union of edge sets of \( Q_L \) and \( Q_R \) equals to the edge set of \( Q_\phi \), and \( N \) is a natural number.

Given a graph \( G \), a pattern \( Q_\phi \) and its sub-pattern \( Q_L \), a match \( G_L \) (resp. \( G_R \)) of \( Q_L \) (resp. \( Q_R \)) is denoted as a \( Q_L \)-value (resp. \( Q_R \)-value) of \( Q_\phi \) in \( G \). Then, we denote by \( G_{\phi}(Q_\phi, Q_{ni}) \) \( Q_L \sim G_L \) the set \( \{G_R | G_R \subseteq G_s, G_R \in Q_R(G), G_L \subseteq G_s, G_s \in Q_\phi(G)\} \), and write it as \( G_{\phi_{Q_L}}(Q_L \sim G_L) \), when \( Q_\phi \) is clear from the context.

A graph \( G \) satisfies the access constraint \( \phi \), if

- for any \( Q_L \)-value \( G_L \), \( |G_{Q_R}(Q_L \sim G_L)| \leq N \); and
- there exists a function (referred to as an index) that given a \( Q_L \)-value \( G_L \), returns \( \{G_s | G_s \in Q_\phi(G), G_L \subseteq G_s\} \) from \( G \) in \( O(N) \) time.

Intuitively, an access constraint \( \phi \) is a combination of a cardinality constraint and an index \( I_\phi \) on \( Q_L \) for \( Q_R \). It tells us that given any \( Q_L \)-value, there exist at most \( N \) distinct \( Q_R \)-values, and these \( Q_R \)-values can be efficiently fetched by using \( I_\phi \). By using indices, we can also construct a fraction \( G_Q \) of \( G \), whose size is bounded by \( \sum_{\varphi \in \mathcal{C}} N_1 \cdot |Q_\varphi| \). We refer to the maximum cardinality of access constraints in an access schema \( \mathcal{C} \) as \( N_m \). A graph \( G \) satisfies access schema \( \mathcal{C} \), denoted by \( G \models \mathcal{C} \), if \( G \) satisfies all the access constraints \( \varphi \) in \( \mathcal{C} \).

Example: An access schema with a single access constraint \( \varphi \) is shown in Fig. 1(d). By definition, pattern \( Q_\varphi \) takes two edges that are from its sub-patterns \( Q_L \) and \( Q_R \), respectively. Assume that an index \( I_\varphi \) is constructed on \( G \) (Fig. 1(a)), then given a \( Q_L \)-value (PM2, DBA1), one can fetch from \( I_\varphi \) a set of matches of \( Q_\varphi \), i.e., \{\{(PM2, DBA1, PRG1), (PM2, DBA1, PRG2)\}\}. One may further verify that \( |G_{Q_R}(Q_L \sim G_L)| = 2 \).

Bounded pattern matching using views. Given a pattern query \( Q \), a set \( \mathcal{V} \) of view definitions and an
access schema $\mathcal{C}$, bounded pattern matching using views is to find another query $\mathcal{A}$ such that for any graph $G$ that satisfies $\mathcal{C}$,

- $\mathcal{A}$ is equivalent to $Q$, i.e., $Q(G) = \mathcal{A}(G)$; and
- $\mathcal{A}$ only refers to views $\mathcal{V}$, their extensions $\mathcal{V}(G)$ in $G$ and $G_Q$ only, without accessing original graph $G$. Here $G_Q$ is a fraction of $G$ and can only be constructed with indexes $\mathcal{I}_\mathcal{C}$, that are associated with access constraints $\varphi \in \mathcal{C}$, such that the time for generating $G_Q$ is in $O(\Sigma_{\varphi_i \in \mathcal{C}} N_i)$, and the size $|G_Q|$ of $G_Q$ is bounded by $O(\Sigma_{\varphi_i \in \mathcal{C}} N_i \cdot |Q_{\varphi_i}|)$.

If such an algorithm $\mathcal{A}$ exists, we say that pattern $Q$ is boundedly evaluable with views, and can be evaluated using $\mathcal{V}(G)$ and a fraction $G_Q$ of $G$ of bounded size, no matter how big $G$ is.

**Remark.** To make practical use of bounded pattern matching using views, it is critical to identify a set of views and access schema. There exist a host of works on view selection based on query logs. For access schema, its identification problem still needs further investigation, while some heuristic methods can be applied. To be more concentrated, this paper mainly focuses on the matching evaluation by using views and access schema.

### 3. Characterization for Bounded Pattern Matching using Views

We propose a characterization for bounded pattern matching using views, i.e., a sufficient and necessary condition for deciding whether a pattern query is boundedly evaluable with views.

#### 3.1. Joint Containment Problem

We first introduce the notion of joint containment.

**Joint containment.** A pattern query $Q$ with edge set $E_p$ is jointly contained by a set of views $\mathcal{V} = \{V_1, \cdots, V_n\}$, and a set of access constraints $\mathcal{C} = \{\varphi_1, \cdots, \varphi_k\}$, denoted by $Q \sqsubseteq_{J} [\mathcal{V}, \mathcal{C}]$, if for any

**Table 1** A summary of notations
where \( \mathcal{G} \) is the graph of the \( i \)-th access constraint \( \varphi_i \) in \( \mathcal{C} \).

Intuitively, \( \varnothing \subseteq \mathcal{J} \) \([\mathcal{V}, \mathcal{C}]\) indicates that \( \varnothing \) can be divided into two disjoint parts, that take edge sets \( E_c \) and \( E_u \), respectively, and \( \varnothing \) is the edge set of the \( j \)-th access constraint \( \varphi_j \) in \( \mathcal{C} \).

**Example:** Recall \( \mathcal{G}, \varnothing, \mathcal{V} \) and \( \mathcal{C} \) in Fig. 1. One may verify that \( \varnothing \subseteq \mathcal{J} \) \([\mathcal{V}, \mathcal{C}]\), since the edge set of \( \varnothing \) can be divided into two parts \( E_c = \{(\text{PM}, \text{BA}_1), (\text{PM}, \text{PRG}), (\text{PRG}, \text{ST}), (\text{PRG}, \text{UI})\} \) and \( E_u = \{(\text{PM}, \text{DBA}_1), (\text{PM}, \text{DBA}_2), (\text{PM}_2, \text{DBA}_1), (\text{PM}_3, \text{DBA}_2)\} \), that are mapped via mappings \( \lambda \) and \( \rho \) to the sets of edges in \( \mathcal{V} \) and \( \mathcal{C} \), respectively. In any graph \( \mathcal{G} \), one may verify that for any edge \( e \) of \( \varnothing \), its match set \( S(e) \) must be a subset of the union of the match sets of the edges in \( \lambda(e) \) or \( \rho(e) \), e.g., \( S(\text{PM}, \text{DBA}) \) in \( \mathcal{G} \) is \( \{(\text{PM}, \text{DBA}_1), (\text{PM}_2, \text{DBA}_1), (\text{PM}_3, \text{DBA}_2)\} \), that is contained in the match set of \( \mathcal{C} \).

**Theorem 1** Given a set of views \( \mathcal{V} \) and an access schema \( \mathcal{C} \), a pattern query \( \varnothing \) is boundedly evaluable with views if and only if \( \varnothing \subseteq \mathcal{J} \) \([\mathcal{V}, \mathcal{C}]\). \( \qed \)

**Proof:** We now prove Theorem 1. (I) We first prove the **only if** condition, i.e., if \( \varnothing \) is boundedly evaluable with views then \( \varnothing \subseteq \mathcal{J} \) \([\mathcal{V}, \mathcal{C}]\). We show this by contradiction. Assume that \( \varnothing \) is boundedly evaluable with views, while \( \varnothing \not\subseteq \mathcal{J} \) \([\mathcal{V}, \mathcal{C}]\). By the definition of **joint containment**, when \( \varnothing \not\subseteq \mathcal{J} \) \([\mathcal{V}, \mathcal{C}]\), there must exist some data graph \( \mathcal{G}_o \), such that for all possible mapping pairs \( \langle \lambda, \rho \rangle \), there always exists at least one edge \( e \) in \( \varnothing \), such that either (a) \( S(e) \not\subseteq \bigcup_{e' \in \lambda(e)} S(e') \) when \( e \) is mapped via \( \lambda \) to \( \mathcal{V} \) or (b) \( S(e) \not\subseteq \bigcup_{e' \in \rho(e)} S(e') \) when \( e \) is mapped via \( \rho \) to \( \mathcal{C} \). Then, there must exist an edge \( e_g \) in \( \mathcal{G}_o \) such that \( e_g \in S(e) \) but \( e_g \not\in \bigcup_{e' \in \lambda(e)} S(e') \) for case (a), or \( e_g \not\in \bigcup_{e' \in \rho(e)} S(e') \) for case (b). No matter which case happens, it contradicts to the assumption that \( \varnothing \) can be answered by using \( \mathcal{V}(\mathcal{G}) \) and \( \mathcal{G}_Q \), since at least for data graph \( \mathcal{G}_o \), one match of \( \varnothing \) with edge \( e_g \) can not be found from \( \mathcal{V}(\mathcal{G}) \) and \( \mathcal{G}_Q \). Thus, \( \varnothing \) is boundedly evaluable with views only if \( \varnothing \subseteq \mathcal{J} \) \([\mathcal{V}, \mathcal{C}]\).

(II) We next show the **if** condition, also by contradiction. Assume that \( \varnothing \not\subseteq \mathcal{J} \) \([\mathcal{V}, \mathcal{C}]\), but \( \varnothing \) is not boundedly evaluable with views. Then there must exist some data graph \( \mathcal{G}_o \) such that \( \mathcal{V}(\mathcal{G}_Q) \) contains a match \( G_s \), that can not be derived from \( \mathcal{V}(\mathcal{G}) \) and \( \mathcal{G}_Q \). As a result, there must exist an edge \( e_g \) in \( G_s \), that is not in \( S(e') \) for any \( e' \) that is mapped either via \( \lambda \) or \( \rho \) from \( \mathcal{G}_o \). This contradicts the assumption, as \( \varnothing \not\subseteq \mathcal{J} \) \([\mathcal{V}, \mathcal{C}]\) (by assumption) already indicates that there exist a pair of mappings \( \langle \lambda, \rho \rangle \) such that \( S(e) \) is a subset of \( \bigcup_{e' \in \lambda(e)} S(e') \) or \( \bigcup_{e' \in \rho(e)} S(e') \) for any \( e \) in \( \mathcal{G}_o \). Putting these together, Theorem 1 follows. \( \qed \)

Theorem 1 shows that **joint containment** determines whether a pattern query is boundedly evaluable with views. This further motivates us to study the **joint containment** (JPC) problem, which is to determine, given a pattern query \( \varnothing \), a set of views \( \mathcal{V} \) and an access schema \( \mathcal{C} \), whether \( \varnothing \subseteq \mathcal{J} \) \([\mathcal{V}, \mathcal{C}]\).

**Remarks.** (1) A special case of **joint containment** is the pattern containment [25]. Indeed, when
access schema \( \mathcal{C} \) is an empty set, joint containment problem becomes pattern containment problem. (2) When \( Q \) is not contained in \( \mathcal{V} \) (denoted as \( Q \nsubseteq \mathcal{V} \)), one may find another pattern query \( Q_g = (V_g, E_g) \), referred to as a containing rewriting of \( Q \) w.r.t. \( \mathcal{V} \), such that \( Q_g \subseteq Q \) and \( Q_g \nsubseteq \mathcal{V} \), compute matches \( Q_g(G) \) of \( Q_g \) from \( \mathcal{V}(G) \) and treat \( Q_g(G) \) as “approximate matches” [25]. While, we investigate more practical but nontrivial cases, i.e., \( Q \nsubseteq \mathcal{V} \), and advocate to integrate access schema into view-based pattern matching such that exact matches can be identified by using a small portion of additional data of bounded size.

3.2. Determination of Joint Containment

To characterize joint containment, a notion of shadow, which is introduced in [25] is required. To make the paper self-contained, we cite it as follows (rephrased).

Given a pattern query \( Q \) and a view definition \( \mathcal{V} \), one can compute \( \mathcal{V}(Q) \) by treating \( Q \) as data graph, and \( \mathcal{V} \) as pattern query. Then the shadow from \( \mathcal{V} \) to \( Q \), denoted by \( H^Q_{\mathcal{V}} \), is defined to be the union of edge sets of matches of \( \mathcal{V} \) in \( Q \).

To ease the presentation, we denote by \( \bar{E}_g = E_p \setminus E_g \) as the “uncovered edges” of \( Q_g \) (a containing rewriting of \( Q \)) in \( Q \), where \( E_p \) and \( E_g \) are the edge sets of \( Q \) and \( Q_g \), respectively.

The result below shows that shadow yields a characterization of joint containment.

For a pattern \( Q \), a set of view definitions \( \mathcal{V} \) and an access schema \( \mathcal{C} \), \( Q \subseteq_J [\mathcal{V}, \mathcal{C}] \) if and only if there exists a containing rewriting \( Q_g \) of \( Q \) such that \( \bar{E}_g \subseteq \bigcup_{\varphi \in \mathcal{C}} H^Q_{\mathcal{V}} \).

**Proof:** (I) We first show the if condition by contradiction. Assume that there exists a containing rewriting \( Q_g \) of \( Q \) with \( \bar{E}_g \subseteq \bigcup_{\varphi \in \mathcal{C}} H^Q_{\mathcal{V}} \), but \( Q \nsubseteq_J [\mathcal{V}, \mathcal{C}] \). Then by the definition of joint containment, there must exist a data graph \( G_o \) with edge \( e_g = (v, v') \), such that \( e_g \) is in \( S(e) \) but not in \( \bigcup_{e' \in \lambda(e)} S(e') \) when \( e \) is mapped via \( \lambda \) to \( \mathcal{V} \), or \( \bigcup_{e' \in \rho(e)} S(e') \) when \( e \) is mapped via \( \rho \) to \( \mathcal{C} \), for an edge \( e = (u, u') \) of \( Q \).

(1) If \( e \) is mapped via \( \lambda \) to \( \mathcal{V} \), then one may verify that \( v, v' \) are matches of \( u, u' \), respectively, while there does not exist a view definition \( \mathcal{V} \) such that \( v \) and \( v' \) can match \( u_v \) and \( u'_v \), simultaneously, where \( (u_v, u'_v) \) is an edge in \( \mathcal{V} \). This indicates that there does not exist a containing rewriting \( Q_g \) of \( Q \) w.r.t. \( \mathcal{V} \).

(2) When \( e \) is mapped via \( \rho \) to an edge \( e_\varphi \) in \( Q_\varphi \) of \( \varphi \), it can be easily verified that \( e_g \) is not \( S(e_\varphi) \). While, by the assumption that \( \bar{E}_g \subseteq \bigcup_{\varphi \in \mathcal{C}} H^Q_{\mathcal{V}} \) and the definition of shadow, for each edge \( e_s = (u_s, u'_s) \) in \( \bar{E}_g \), there must exist at least one \( \varphi \) such that \( u_s, u'_s \) are the matches of \( u_v, u'_v \), respectively, where \( (u_v, u'_v) \) is an edge in \( Q_\varphi \) of \( \varphi \). Accordingly, one may further verify that nodes \( v, v' \) in \( G \), that are matches of \( u, u' \), must also be matches of \( u_v, u'_v \) by the semantic of subgraph isomorphism. Thus, \( e_g \) must be in \( \bigcup_{e' \in \rho(e)} S(e') \), which contradicts the assumption.

Putting these together, the contradiction is incorrect.

(II) For the Only If condition, we assume by contradiction that \( Q \subseteq_J [\mathcal{V}, \mathcal{C}] \), but there does not exist a containing rewriting \( Q_g \) of \( Q \) with \( \bar{E}_g \subseteq \bigcup_{\varphi \in \mathcal{C}} H^Q_{\mathcal{V}} \). By the assumption that there does not exist a containing rewriting \( Q_g \) of \( Q \) w.r.t. \( \mathcal{V} \), or \( \bar{E}_g = \bigcup_{\varphi \in \mathcal{C}} H^Q_{\mathcal{V}} \). For case (a), one may verify that there does not exist a mapping from \( E_o \) to \( \mathcal{V} \) satisfying \( S(e) \subseteq \bigcup_{e' \in \lambda(e)} S(e') \) for any edge \( e \in E_o \); for case (b), it can also be verified that no mapping from \( E_u \) to \( \mathcal{C} \) with \( S(e) \subseteq \bigcup_{e' \in \rho(e)} S(e') \) for any edge \( e \in E_u \) exists. Either of two cases leads to the contradiction of \( Q \subseteq_J [\mathcal{V}, \mathcal{C}] \).

These complete the proof of Proposition.
### Theorem 2

(1) The JPC problem is NP-hard. (2) It is in \(O(||\mathcal{V}|| + ||\mathcal{C}||Q||Q||)\) time to decide whether \(Q \sqsubseteq J [\mathcal{V}, \mathcal{C}]\), and if so, to compute associated mappings from \(Q\) to \(\mathcal{V}, \mathcal{C}\).

#### Proof

We first show Theorem 2(1). We then show Theorem 2(2) by presenting an algorithm as a constructive proof.

(I) We show NP-hardness of the JPC problem by reduction from the NP-complete subgraph isomorphism problem (ISO) [10].

An instance of ISO consists of a graph \(G_1 = (V_1, E_1)\) and a pattern \(Q_1 = (V_{p_1}, E_{p_1})\). ISO is to decide whether there exists a subgraph \(G_2\) in \(G_1\) that is isomorphic to \(Q_1\). Given such an instance of ISO, we construct an instance of JPC problem as follows: (a) we create a pattern query \(Q\) that takes the same node and edge set as \(G_1\); (b) we create a view set \(\mathcal{V}\) that takes a single view definition \(\mathcal{V}\) and let \(\mathcal{V}\) equal to \(Q_1\); and (c) we create an access schema \(\mathcal{C}\) that only includes a single access constraint \(\varphi\) and let \(Q_\varphi\) take edges in \(Q\) but not in \(\mathcal{V}\). The construction is obviously in \(\text{PTIME}\). We next verify that there exists a subgraph \(G_2\) of \(G_1\) that is isomorphic to \(Q_1\) if and only if \(\bar{E}_g \subseteq \bigcup_{e \in E} H^Q_{Q_\varphi}\).

Assume that there exists a subgraph \(G_s\) as a match of \(Q_1\) in \(G_1\), one can verify that \(\bar{E}_g\) consists of edges in \(G_1\) but not \(G_s\), and \(H^Q_{Q_\varphi}\) includes edges of \(E_1 \setminus E_{p_1}\). Thus \(\bar{E}_g \subseteq \bigcup_{e \in E} H^Q_{Q_\varphi}\). Conversely, if \(\bar{E}_g \subseteq \bigcup_{e \in E} H^Q_{Q_\varphi}\), it can be easily verified that a pattern with edge set \(E_1 \setminus \bar{E}_g\) is a match of \(Q_1\).

As ISO is NP-complete, so JPC problem is NP-hard.

(II) We show Theorem 2(2) with an algorithm and its analysis.

#### Algorithm

The algorithm, denoted as JCont, takes \(Q, \mathcal{V}\) and \(\mathcal{C}\) as input, and returns true if and only if \(Q \sqsubseteq J [\mathcal{V}, \mathcal{C}]\). The algorithm works in three stages. In the first stage, it initializes a boolean variable \(\text{ans}\), and three empty sets \(E_c, E_u\) and \(C'\), to keep track of “covered edges”, “uncovered edges”, and selected access constraints, respectively (line 1). In the second stage, it identifies an edge set \(E_c\) such that the sub-pattern of \(Q\) induced with \(E_c\) is contained by \(\mathcal{V}\). Specifically, it (1) computes shadow \(H^Q_{V_i}\) for each \(V_i\) in \(\mathcal{V}\), by invoking the revised subgraph isomorphism algorithm, which finds all the matches of \(V_i\) in \(Q\) with algorithm in [10], and then merges them together; (2) extends \(E_c\) with \(H^Q_{V_i}\) (lines 2-3). After all the shadows are merged, JCont generates an edge set \(E_u = E_p \setminus E_c\) (line 4).
the last stage, JCont verifies the condition for joint containment as follows. It checks for each access constraint \( \varphi \) whether its \( Q_{\varphi} \) can cover a part of \( E_u \), i.e., \( H_{Q_{\varphi}}^Q \cap E_u \neq \emptyset \) (line 6). If so, JCont enlarges \( C' \) with \( \varphi \) and updates \( E_u \) with \( E_u \setminus H_{Q_{\varphi}}^Q \) (line 7). When the condition \( E_u = \emptyset \) is encountered, the variable ans is changed to true, and the for loop (line 5) immediately terminates (line 9). JCont finally returns ans as result (line 10).

**Example:** Recall \( Q, \mathcal{V} = \{V_1, V_2\} \) and \( C = \{\varphi\} \) in Fig. 1. JCont first computes shadows for each \( V_i \in \mathcal{V} \) and obtains \( H^Q_{\mathcal{V}_1} = \{(PM, BA), (PM, PRG)\} \), \( H^Q_{\mathcal{V}_2} = \{(PRG, ST), (PRG, UI)\} \). Then \( E_u \) contains \( \{(PM, DBA), (PRG, DBA)\} \). It next computes \( H_{Q_{\varphi}}^Q \) that exactly covers \( E_u \). Lastly, JCont returns true indicating that \( Q \) is boundedly evaluable with views. □

**Correctness.** The correctness is ensured by that when JCont terminates, JCont correctly identifies a part \( Q_{\varphi} \) (with edge set \( E_{\varphi} \)) of \( Q \) that can be answered by using \( \mathcal{V} \); and in the meanwhile, the remaining part \( Q_{\lambda} \) (with edge set \( E_{\lambda} \)) of \( Q \) can also be covered by \( C \). To see this, observe the following. (1) JCont always terminates, since two for loops (lines 2-3, 5-9) execute \( ||\mathcal{V}|| \) and \( ||C|| \) times, respectively. (2) When JCont terminates, (a) \( Q_{\varphi} \) consists of edges of shadows from each view \( \mathcal{V} \), i.e., \( \bigcup_{V_i \in \mathcal{V}} H^Q_{\mathcal{V}_i} \). Thus, \( Q_{\varphi} \) is contained by \( \mathcal{V} \) and can be answered using \( \mathcal{V}(G) \). (b) \( E_{\lambda} \) includes edges of shadows from each \( Q_{\lambda} \) to \( Q \), showing how many uncovered edges of \( Q \) can be covered by using \( C \). When \( E_u \) turns to an empty set, i.e., all the uncovered edges can be covered, JCont changes ans to true, indicating that \( Q \subseteq_j [\mathcal{V}, C] \).

**Complexity.** The initialization of JCont is in constant time. For the second stage, JCont iteratively computes shadow \( H^Q_{\mathcal{V}_i} \) for each \( V_i \in \mathcal{V} \). As it takes \( O(||Q||!||Q||) \) time to compute shadow from \( V_i \) to \( Q \) for a single iteration, and the for loop repeats \( ||\mathcal{V}|| \) times, thus, it is in \( O(||\mathcal{V}||!||Q||!||Q||) \) time for the second stage. In the last stage, JCont computes shadow from \( Q_{\varphi} \) to \( Q \) for each access constraint \( \varphi \) in \( C \), which is in \( O(||Q||!||Q||) \) time for a single iteration as well. As the iteration executes \( ||C|| \) times, it hence takes \( O(||\mathcal{V}||!||Q||!||Q||) \) time. Putting these together, JCont is in \( O(||\mathcal{V}|| + ||C||!||Q||!||Q||) \) time.

**Remarks.** (1) There already exist techniques, e.g., [25] to answer graph pattern matching using views only. Indeed, after containment checking (lines 2-4 of JCont), if \( E_u \) becomes an empty set, then pattern \( Q \) is contained in \( \mathcal{V} \), indicating that pattern \( Q \) can be answered by using views only, without access constraints. While, in this paper, we are focusing on nontrivial pattern queries \( Q \), i.e., \( Q \not\subseteq \mathcal{V} \), then \( E_u \) is enforced to be a nonempty set after containment checking. (2) Algorithm JCont can be easily adapted to return a pair of mappings \( \langle \lambda, \rho \rangle \) that serve as input for the matching algorithm (will be given in Section 4).

4. Matching Evaluation

In this section, we study how to evaluate pattern matching using views \( \mathcal{V}(G) \) and a fraction \( G_Q \) of \( G \). We first develop an algorithm to find matches from \( \mathcal{V}(G) \) and \( G_Q \). We next study the minimum containment problem, to optimize the matching evaluation.

4.1. An Matching Algorithm

Along the same line as pattern matching using views, on a graph \( G \) that satisfies access schema \( C \), a pattern query \( Q \) can be answered with \( \mathcal{V}(G) \) and \( G_Q \) as following: (1) determine whether \( Q \subseteq_j [\mathcal{V}, C] \) and compute a pair of mappings \( \langle \lambda, \rho \rangle \) with revised algorithm of JCont; and (2) compute \( Q(G) \) with
Input: Pattern $Q$, views $V$, $\mathcal{V}(G)$, access schema $\mathcal{C}$, mappings $\lambda$, $\rho$.
Output: The query result $M$ as $Q(G)$.

1. initialize an empty pattern $Q_s$; set $M := \emptyset$, $M_1 := \emptyset$;
2. for each view $V_i$ that is mapped via $\lambda$ from $E_\rho$ do
   3. for each $G_s \in \lambda^{-1}(V_i)$ do
      4. $Q_o \oplus G_s$;
      5. for each $m_1 \in M$ and each $m_2 \in \mathcal{V}_i(G)$ do
         6. if $m_1$ and $m_2$ can be merged then
            7. $m := m_1 \oplus m_2$; $M_1 := M_1 \cup \{m\}$;
            8. update $M$, $M_1$;
   9. for each access constraint $\varphi$ in $\rho(E_\rho)$ do
   10. $\langle Q_o, M \rangle := \text{Expand}(Q_o, M, \varphi, \rho)$;
11. return $M$;

Fig. 3 Algorithm BMatch

an matching algorithm that takes $\lambda$, $\rho$, $V$, $\mathcal{V}(G)$ and $\mathcal{C}$ as input, if $Q \sqsubseteq_j [V, \mathcal{C}]$. We next show that such a matching algorithm indeed exists.

**Theorem 3** For any graph $G$ that satisfies access schema $\mathcal{C}$, a pattern $Q$ can be answered by using $V$, $\mathcal{V}(G)$ and $G_Q$ in $O((|V|^{|Q|}\|\mathcal{V}(G)\|)|V||\|Q||N_m\|\!|\mathcal{C}|\!|)$ time, if $Q \sqsubseteq_j [V, \mathcal{C}]$. \hfill $\square$

**Proof:** We next provide an algorithm with detailed analyses as a constructive proof of Theorem 3.

**Algorithm.** The algorithm, denoted as BMatch, is shown in Fig. 3. It takes a pattern $Q$, a set of views $V$ and $\mathcal{V}(G)$ and mappings $\lambda$ and $\rho$, as input, and works in two stages: “merging” views $\mathcal{V}_i(G)$ following the mapping $\lambda$; and “expanding” partial matches with $G_Q$ under the guidance of mapping $\rho$.

More specifically, BMatch starts with an empty pattern query $Q_o$, an empty set $M$ to keep track of matches of $Q_o$ and another empty set $M_1$ for maintaining intermediate results (line 1). It then iteratively “merges” $V_i(G)$ following mapping $\lambda$ (lines 2-8). Specifically, for each view definition $V_i$ that is mapped via $\lambda$ from edge set $E_\rho$ (line 2) and each match $G_s$ of $V_i$ in $Q$ (line 3), BMatch expands $Q_o$ with $G_s$ (line 4), and iteratively expands each match $m_1$ of $Q_o$ with each match $m_2$ of $V_i$ if they can be merged in the same way as the merging process of $Q_o$ and $G_s$, and includes the new match $m$ in $M_1$ (lines 5-7). When a round of a merging process for matches of $Q_o$ and $V_i$ finished, BMatch updates $M$ and $M_1$ by letting $M := M_1$ and $M_1 := \emptyset$ (line 8). When the first stage finished, $Q_o$ turns to a containing rewriting of $Q_o$ of $Q$ and $M$ includes all the matches of $Q_o$ in $G$. In the following stage, BMatch iteratively invokes Procedure Expand to “expand” $Q_o$ and its matches under the guidance of mapping $\rho$ (lines 9-10). It finally returns $M$ as matches of $Q(G)$ (line 11).

**Procedure Expand.** Given mapping $\rho$, access constraint $\varphi$, pattern $Q_o$ and its match set $M$, Expand (not shown) expands $Q_o$ and $M$ as follows. It first initializes an empty set $M_1$. For each match $G_s$ of $Q_o$ in $Q$, Expand first extends $Q_o$ with $G_s$; it next expands a match $m_1$ of $Q_o$ with a match $G_L$ of $Q_L$ if $m_1$ has common nodes or edges with $G_L$ and further expands $m_1$ with each $Q_R$-value $G_R$ of $G_L$, for each match $m_1$ of $Q_o$ and each match $G_L$ of $Q_L$. The new matches are maintained by the set $M_1$. After all the $G_s$ are processed, Expand returns updated $Q_o$ and its match set $M_1$ as final result.

**Example:** Consider $Q$, $V$, $\mathcal{V}(G)$ and $\varphi$ shown in Fig. 1. BMatch first merges “partial matches” in $\mathcal{V}(G)$ following the guidance of mapping $\lambda$. Specifically, it first initializes $Q_o$ and $M$ with $V_1$ and $V_1(G)$ (as shown in Fig. 1(c)); it next expands $Q_o$ with $V_2$, and merges each match in $M$ with each
match in $V_2(G)$. After “partial matches” are merged, $Q_o$ includes all the edges of $V_1$ and $V_2$, and set $M$ contains following matches.

</table>

Guided by mapping $\rho$, BMatch expands $Q_o$ and its matches via Procedure Expand. Expand first merges $Q_o$ with $Q_o$. Then, it first expands $m_1$ with $G_L$ (with edge set $\{(PM_1, DBA_1)\}$), and then merges $m_1$ with $G_R$ (with edge set $\{(PRG_1, DBA_1)\}$). The above merge process repeats another 5 times for each $m_i$ ($i \in [2, 6]$). Finally, BMatch returns a set of 6 matches that are grown from $m_1 - m_6$, respectively.

Correctness. The correctness is guaranteed by the following three invariants: (1) BMatch correctly merges $Q_o$ (resp. $M$) with views $V_i$ (resp. $V_i(G)$); (2) procedure Expand correctly expands $Q_o$, and $M$ using indexes associated with access schema; and (3) when BMatch terminates, $Q_o$ (resp. $M$) is equivalent to $Q$ (resp. $Q(G)$). To see these, observe the following:

1. Mappings $\lambda$ and $\rho$ essentially split pattern $Q$ into two parts: $Q_c$ with edge set $E_c$ and $Q_o$ with edge set $E_o$. These two parts are “covered” by $V$ and $C$, respectively.
2. A view $V_i$ can be mapped to different parts of $Q_o$, via $\lambda^{-1}$. BMatch hence merges $Q_o$ with each match $G_s$ of $V_i$ in $Q$ (lines 3-4). This merge process also guides the merge of matches of $Q_o$ with matches of $V_i$ as follows: if a match $m_2$ of $V_i$ can be merged with a match $m_1$ of $Q_o$, along the same line as the merge of $Q_o$ and $G_s$, then $m_1$ and $m_2$ are merged as a whole (lines 5-7). These guarantee that when a new round merging process terminates, a new pattern query, that expands $Q_o$ with the shadow of $V_i$ in $Q_o$, is formed, and the set $M$ includes all the matches of the new pattern query.
3. Guided by $\rho^{-1}$, $Q_o$ in $\varphi$ can also be mapped to various parts $G_s$ of $Q$. Thus Expand iteratively expands $Q_o$ with those $G_s$. When the outmost loop terminates (line 2), $Q_o$ has been enlarged with the entire shadow of $Q_R$ in $Q_o$. During the expansion of $Q_o$, Expand first fetches a set of matches $G_L$ of $Q_L$ from index $I_o$. For each match $m_1$ of $Q_o$ and each match $G_L$ of $Q_L$, if they overlap each other; Expand merges $m_1$ with $G_L$ first and then expands $m_1$ for each $Q_R$-value of $G_L$. Thus, it can be easily verified that each match $G_L$ of $Q_L$ and the corresponding $Q_R$-value of $G_L$ will not be missed, during expansion, which ensures that $M_1$ correctly maintains matches of $Q_o$.
4. When two for loops (lines 2-7 and 8-9) of BMatch terminate, $Q_o$ must be equivalent to $Q$, as edges in $E_c$ and edges in $E_u$ are all covered, in the meanwhile, $M$ must contain a complete set of matches of $Q_o$, guaranteed by observations given above.

Complexity. We give a detailed complexity analysis as below.

I. BMatch iteratively merges $Q_o$ and $M$ with view $V_i$ and $V_i(G_i)$, respectively. For a single iteration, it takes $BMatch |\lambda^{-1}(V_i)||M||V_i(G_i)|$ time for the “merge” task. As in the worst case, (1) there may exist $|V_i||Q_o|_i$ matches of $V_i$ in $Q_o$, where $V_i$ denotes the node set of $V_i$ and $|Q_o|$ is bounded by $|Q|$, hence $|\lambda^{-1}(V_i)|$ is bounded by $|V_i||Q_o|_i$; (2) $|M|$ is bounded by $\prod_{i \in [1,k-1]}|V_i||Q_o|_i|V_i(G_i)|$ before the $k$-th iteration; and (3) the iteration repeats at most $|V_i|_i$ times, hence the first stage is bounded by $\prod_{i \in [1,|V_i|]}|V_i||Q_o|_i|V_i(G_i)|$, which is in $O((|V_i||Q_o|_i|V_i(G_i)|)|V_i|)$ time.

II. BMatch repeatedly invokes Procedure Expand to process expansion of $Q_o$ and $M$ with access constraint $\varphi$. For a single process, it takes $\prod_{\rho^{-1}(Q_R)||M||I_o(G_L)}$ time. Note that (1)
380  Bounded Graph Pattern Matching With View

Before the \( B \)-Match times, the second stage is hence in \( O(k) \) weight no more than \( \log(|Q|) \), as \(|Q|\) is bounded by \(|Q|\); (2) \(|M|\)'s bounded by \(||V||V(G)||||V||\cdot \prod_{i=1,k-1}|V_{R,p}| \cdot N_i|\), before the \( k \)-th iteration; and (3) \(|I_{2i}(G_L)| \leq N_k\) at the \( k \)-th iteration, thus, \( \text{Expand} \) is in \( O(|V||Q| \cdot (|V||Q|V(G)||)|\prod_{i=1,k-1}|V_{R,p}| \cdot N_i) \) time. As the iteration repeats at most \(|C|\) times, the second stage is hence in \( O(|V||Q|(|V||Q|V(G)||)|\prod_{i=1,k-1}|V_{R,p}| \cdot N_m|C|) \) time. Putting these together, \( B \)-Match is in \( O(|V||Q|V(G)||)|\prod_{i=1,k-1}|V_{R,p}| \cdot N_m|C|) \) time, where \( N_m \) is the maximum cardinality of access schema \( C \). □

4.2. Optimization Strategy

As the cost of \( B \)-Match is partially determined by \(|V(G)|\) and \(|G_Q|\), it is hence beneficial to reduce the size of the parameters. This motivates us to study the minimum containment problem.

Minimum Containment Problem. Given a pattern query \( Q \), a set of view definitions \( V \) with each \( V_i \) associated with weight \(|V_i(G)|\), and an access schema \( C \), the problem, denoted as \( \text{MCP} \), is to find a subset \( V' \) of \( V \) and a subset \( C' \) of \( C \), such that (1) \( Q \subseteq [V', C'] \), and (2) for any subset \( V'' \) of \( V \) and any subset \( C'' \) of \( C \), if \( Q \subseteq [V'', C''] \), then \(|V''(G)| + \Sigma_{\varphi \in C'' \cdot N_i \cdot |Q_{\varphi_i}|} \leq |V''(G)| + \Sigma_{\varphi \in C'' \cdot N_i \cdot |Q_{\varphi_i}|} \).

As will be seen in Section 4, \( \text{MCP} \) is effective: it can eliminate redundant views (as well as their corresponding extensions), and reduce the size of \( G_Q \) thereby improving the efficiency of \( B \)-Match. However, \( \text{MCP} \) is nontrivial, its decision problem is \( \text{NP} \)-hard. Despite of this, we develop an algorithm for \( \text{MCP} \), which is approximable within \( O(\log(|Q|)) \). That’s, the algorithm can identify a subset \( V' \) of \( V \) and a subset \( C' \) of \( C \) when \( Q \subseteq [V', C'] \), such that \( Q \subseteq [V', C'] \) and \(|V'(G)| + \Sigma_{\varphi \in C' \cdot N_i \cdot |Q_{\varphi_i}|} \) is guaranteed to be no more than \( \log(|Q|) \cdot (|V_{\text{OPT}}(G)| + \Sigma_{\varphi \in C' \cdot N_i \cdot |Q_{\varphi_i}|}) \), where \( V_{\text{OPT}} \) and \( C_{\text{OPT}} \) are the subsets of \( V \) and \( C \), respectively, and moreover, \( Q \subseteq [V_{\text{OPT}}, C_{\text{OPT}}] \) and \(|V_{\text{OPT}}(G)| + \Sigma_{\varphi \in C_{\text{OPT}} \cdot N_j \cdot |Q_{\varphi_j}|} \) is minimum, among all possible subset pairs of \( V \) and \( C \).

Theorem 4 The \( \text{MCP} \) is (1) \( \text{NP} \)-hard (decision problem), but (2) there exists an algorithm for \( \text{MCP} \) that finds a subset \( V' \) of \( V \) and a subset \( C' \) of \( C \) with \( Q \subseteq [V', C'] \) and \(|V'(G)| + \Sigma_{\varphi \in C' \cdot N_i \cdot |Q_{\varphi_i}|} \) \(|Q_{\varphi_i}| \leq \log(|Q|) \cdot (|V_{\text{OPT}}(G)| + \Sigma_{\varphi \in C_{\text{OPT}} \cdot N_j \cdot |Q_{\varphi_j}|}) \) in \( O(|V||Q|||Q|^3/2) \) time. □

Proof. We now prove Theorem 4 (1) and (2), respectively.

(1) We prove \( \text{NP} \)-hardness of \( \text{MCP} \) by showing \( \text{NP} \)-hardness of its special case, i.e., when access schema \( C \) is an empty set. The decision problem of the special case is to determine, given a pattern query \( Q \), a set of view definitions \( V = \{V_1, \ldots, V_n\} \) with each \( V_i \) taking integer weight \(|V_i(G)|\) \((i \in [1, n])\), and an integer \( B \), whether there exists a subset \( V' \) of \( V \) such that \( Q \subseteq V' \) and \(|V'(G)| \leq B \).

We show that this problem is \( \text{NP} \)-hard by reduction from the set cover problem (SCP) [23], which is known \( \text{NP} \)-complete. An instance of SCP consists of a set \( U \), a collection of subsets of \( U \), \( S = \{S_1, \ldots, S_n\} \), where each subset \( S_i \) takes integer weight \( \omega(S_i) \), and an integer \( K \). SCP is to decide whether there exists a subset \( S' \) of \( S \) that covers \( U \), i.e., \( \bigcup_{S_i \in S} S_i = U \), and \( S' \) has total weight no more than \( K \). Given such an instance of SCP, we construct an instance of \( \text{MCP} \) as follows: (a) for each \( x_i \in U \), we create a unique edge \( e_{x_i} \) with two distinct nodes \( u_{x_i} \) and \( v_{x_i} \); (b) we define a pattern query \( Q \) as a graph consisting of all edges \( e_{x_i} \) defined in (a); (c) we construct a set \( V \), and define each view definition \( V_i \) in \( V \) taking edges \( e_{x_i} \) and weight \( \omega(S_j) \) from \( S_j \), for each subset \( S_j \in S \) and \( x_i \in S_j \); and (d) we set \( K = B \).

The construction is obviously in \( \text{PTIME} \). We next verify that there exists a subset \( S' \) of \( S \) with total weight no more than \( K \) if and only if there exists a subset \( V' \) of \( V \) such that \( Q \) is contained in \( V' \) and
Input: A pattern \( Q = (V_p, E_p) \), a set of views \( \mathcal{V} \), an access schema \( \mathcal{C} \).
Output: A subset \( \mathcal{V}' \) of \( \mathcal{V} \) and a subset \( \mathcal{C}' \) of \( \mathcal{C} \) such that \( Q \subseteq [\mathcal{V}', \mathcal{C}'] \).

1. initialize sets \( \mathcal{V}' := \emptyset, \mathcal{C}' := \emptyset, \mathcal{F} := \emptyset \);
2. for each view definition \( V_i \in \mathcal{V} \)
do
3. compute \( H_Q^{V_i} \); \( \mathcal{F} := \mathcal{F} \cup \{ (H_Q^{V_i}, |V_i(G)|) \} \);
4. for each access constraint \( \varphi_j \in \mathcal{C} \)
do
5. compute \( H_Q^{\varphi_j} \); \( \mathcal{F} := \mathcal{F} \cup \{ (H_Q^{\varphi_j}, N_j \cdot |Q_{\varphi_j}|) \} \);
6. \( (\mathcal{V}', \mathcal{C}') := \text{PtnFinder}(Q, \mathcal{F}) \);
7. return \( (\mathcal{V}', \mathcal{C}') \);

Procedure PtnFinder
Input: A pattern query \( Q = (V_p, E_p) \), set \( \mathcal{F} \).
Output: \( (\mathcal{V}', \mathcal{C}') \).

1. initialize an empty pattern \( Q_o = (V_o, E_o) \), set \( \mathcal{V}' := \emptyset, \mathcal{C}' := \emptyset \);
2. while \( \mathcal{F} \neq \emptyset \) do
3. find an object \( \text{obj} \) with the least \( \alpha(\cdot) \) value;
4. if \( (H_Q^{\text{obj}} \setminus Q_o) = \emptyset \) then break;
5. update \( \mathcal{F} \); \( Q_o \) merges \( H_Q^{\text{obj}} \);
6. if \( \text{obj} \) is a view \( V_i \) then \( \mathcal{V}' := \mathcal{V}' \cup \{ V_i \} \);
7. else if \( \text{obj} \) is an access constraint \( \varphi_j \) then \( \mathcal{C}' := \mathcal{C}' \cup \{ \varphi_j \} \);
8. if \( E_o \neq E_p \) then return \( \emptyset \);
9. return \( (\mathcal{V}', \mathcal{C}') \);

Fig. 4 Algorithm Minimum

has total weight \( \Sigma_{V_j \in \mathcal{V}'} |V_j(G)| \) no larger than \( B \).

1. Assume that there exists a subset \( S' \) of \( S \) that covers \( U \) with total weight at most \( K \). Let \( \mathcal{V}' \) be the set of views \( V_j \) corresponding to \( S_j \in S' \). One can verify that \( Q \subseteq \mathcal{V}' \) and \( \Sigma_{V_j \in \mathcal{V}'} |V_j(G)| \leq B \), since the union of all the edges from these \( S_Q \) is \( E_Q \), and the weight \( |V_j(G)| = \omega(S_j) \) for each \( V_j \) in \( \mathcal{V}' \).

2. Conversely, if there exists a subset \( \mathcal{V}' \) of \( \mathcal{V} \) with \( Q \subseteq \mathcal{V}' \) and \( \Sigma_{V_j \in \mathcal{V}'} |V_j(G)| \leq B \), it is easy to see that the corresponding subset \( S' \) of \( S \) has total weight no more than \( K \) and covers \( U \).

As SCP is \( \text{NP} \)-complete, so is \( \text{NP} \)-hardness of MCP.

(II) We next show Theorem 4(2) by providing an approximation algorithm as a constructive proof.

Algorithm. The algorithm, denoted as Minimum, is shown in Fig. 4. Given a pattern query \( Q \), a set of view definitions \( \mathcal{V} \) with each \( V_i \) in \( \mathcal{V} \) taking a weight \( |V_i(G)| \), and an access schema \( \mathcal{C} \), Minimum identifies a pair \( (\mathcal{V}', \mathcal{C}') \) of subsets of \( \mathcal{V} \) and \( \mathcal{C} \) such that (1) \( Q \subseteq \mathcal{V}' \) and \( \Sigma_{V_j \in \mathcal{V}'} |V_j(G)| \leq B \), and (2) \( |\mathcal{V}'(G)| + \Sigma_{\varphi_j \in \mathcal{C}'} (N_j \cdot |Q_{\varphi_j}|) \leq \log(|Q|) \cdot (|\mathcal{V}_{\text{OPT}}(G)| + \Sigma_{\varphi_j \in \text{C}_{\text{OPT}}(N_j \cdot |Q_{\varphi_j}|)) \), where (a) \( \log(|Q|) \) is the approximation ratio, and (b) \( \mathcal{V}_{\text{OPT}}, \mathcal{C}_{\text{OPT}} \) are the subsets of \( \mathcal{V}, \mathcal{C} \), respectively, and moreover, \( Q \subseteq [\mathcal{V}_{\text{OPT}}, \mathcal{C}_{\text{OPT}}] \) and \( |\mathcal{V}_{\text{OPT}}(G)| + \Sigma_{\varphi_j \in \text{C}_{\text{OPT}}(N_j \cdot |Q_{\varphi_j}|) \) is minimum, among all possible subset pairs of \( \mathcal{V} \) and \( \mathcal{C} \).

In a nutshell, the algorithm applies a greedy strategy to find a views \( V_i \) in \( \mathcal{V} \) or an access constraint \( \varphi_j \) from \( \mathcal{C} \) that is considered “best” during the iteration. To measure the goodness of the views and access constraints, we define a metric \( \alpha(V_i) = \frac{|V_i(G)|}{H_Q^{V_i} \setminus Q_o} \) for a view \( V_i \), and \( \alpha(\varphi_j) = \frac{N_j \cdot |Q_{\varphi_j}|}{H_Q^{\varphi_j} \setminus Q_o} \) for an access constraint \( \varphi_j \). Here, \( Q_o \) takes edges from shadows whose corresponding views (resp. access constraints) are chosen in \( \mathcal{V}' \) (resp. \( \mathcal{C}' \)). Intuitively, \( \alpha(V_i) \) (resp. \( \alpha(\varphi_j) \)) indicates how costly it is to “cover” the remaining part \( Q \setminus Q_o \) of \( Q \) with \( H_Q^{V_i} \) (resp. \( H_Q^{\varphi_j} \)), hence a \( V_i \) or \( \varphi_j \) with the least \( \alpha(\cdot) \)
is favored in each round iteration.

The algorithm works in two stages.

(I) It initializes three empty sets \( V', C' \) and \( F \) (line 1), and computes the shadow \( H^Q_{Q_{\varphi_j}} \) for each \( V_i \in V \) (resp. \( H^Q_{Q_{\varphi_j}} \) for each \( \varphi_j \in C \)) and maintains a pair \( \langle H^Q_{V_i}, |V_i(G)| \rangle \) (resp. \( \langle H^Q_{Q_{\varphi_j}}, N_j \cdot |Q_{\varphi_j}| \rangle \)) in \( F \) (lines 2-5). Intuitively, \( |V_i(G)| \) (resp. \( N_j \cdot |Q_{\varphi_j}| \)) can be viewed as the “weight” of its corresponding \( V_i \) (resp. \( \varphi_j \)).

(II) Minimum invokes procedure \( \text{PtnFinder} \) to compute a pair \( \langle V', C' \rangle \) of subsets of \( V \) and \( C \). Specifically, it first initializes an empty pattern query \( Q_o \) and two empty sets \( V', C' \) (line 1). It then iteratively selects an object \( o \) whose corresponding \( \alpha(\cdot) \) is the least (line 3). Here, the chosen object \( o \) is either a view definition \( V_i \) or an access constraint \( \varphi_j \). Once there does not exist any \( o \) whose corresponding shadow can expand \( Q_o \), i.e., \( (H^Q_{Q_{\varphi_j}} \setminus Q_o) = \emptyset \), \( \text{PtnFinder} \) breaks the loop (line 4). Otherwise, it updates \( F \) by removing \( \langle H^Q_{Q_{\varphi_j}}, |V_i(G)| \rangle \) (resp. \( \langle H^Q_{Q_{\varphi_j}}, N_j \cdot |Q_{\varphi_j}| \rangle \)), and expands \( Q_o \) with shadow \( H^Q_{Q_{\varphi_j}} \) (line 5). If \( o \) is a view \( V_i \), \( \text{PtnFinder} \) includes it in \( V' \) (line 6), otherwise, \( \text{PtnFinder} \) enriches \( C' \) with \( \varphi_j \) (line 7). After \textbf{while} loop terminates, if \( E_o \) is not equivalent to \( E_P \), \( \text{PtnFinder} \) returns an empty set, since \( Q \not\subseteq \bigcup_j \{ V, C \} \) and hence no subset pair exists (line 8). Otherwise, \( \text{PtnFinder} \) returns \( \langle V', C' \rangle \) as final result (line 9).

We next provide detailed analysis for the algorithm Minimum.

Correctness. Observe that Minimum either finds a pair \( \langle V', C' \rangle \) of subsets of \( V \) and \( C \) such that \( Q \subseteq \bigcup_j \{ V', C' \} \) or an empty set indicating \( Q \not\subseteq \bigcup_j \{ V, C \} \). This is ensured by joint containment checking of the algorithm (line 8 of \( \text{PtnFinder} \)), by following Proposition 5. Moreover, \( \text{PtnFinder} \) identifies \( \langle V', C' \rangle \) with a greedy strategy, which is verified to guarantee \( \log(|Q|) \) approximation ratio for \textit{weighted set cover problem} [23].

Complexity. Algorithm Minimum computes “shadows” for each \( V_i \) in \( V \) and each \( \varphi_j \) in \( C \) in \( O(||V|| + ||C|| |Q| ||Q|) \) time (lines 2-5). The procedure \( \text{PtnFinder} \) is in \( O((||V|| + ||C|| |Q|))^{3/2}) \) time, as the \textbf{while} loop is executed \( \min\{||V|| + ||C||, |Q|\} \) times, which is bounded by \( O((||V|| + ||C|| |Q|)^{1/2}) \) time, and each iteration takes \( O(||V|| + ||C|| |Q|) \) time to find a view with least \( \alpha(\cdot) \) [23]. Thus, Minimum is in \( O((||V|| + ||C|| |Q|) ||Q| + (||V|| + ||C|| |Q|)^{3/2}) \) time.

The analysis above completes the proof of Theorem 4.

Example: Recall pattern query \( Q \) in Fig. 1 (b). Given a set of views \( V = \{ V_1, \cdots, V_6 \} \) and an access schema \( C = \{ \varphi_1, \varphi_2 \} \), as shown in Fig. 5, algorithm Minimum identifies \( \langle V', C' \rangle \) from \( V \) and \( C \) as following. It first computes shadows for each \( V_i \) in \( V \) and each \( \varphi_j \) in \( C \), and initializes set \( F \) as table below. It next applies \( \text{PtnFinder} \) to iteratively select \( V_1 \) (resp. \( \varphi_2 \)) based on their \( \alpha(\cdot) \) values. Assume \( N_1 \) of \( \varphi_2 \) is 6 and \( N_2 \) of \( \varphi_2 \) is 4 (their actual occurrences in \( G \) of Fig. 1 (a)). Then, \( \text{PtnFinder} \) successively selects \( V_2, \varphi_1 \) and \( V_1 \) to enrich \( V' \) and \( C' \), and terminates \textbf{while} loop. Minimum finally returns \( V' = \{ V_1, V_2 \} \) and \( C' = \{ \varphi_1 \} \) as result.
5. Experimental Evaluation

Using real-life and synthetic data, we conducted three sets of tests to evaluate (1) performances of algorithms for joint containment checking, i.e., the efficiency of algorithm JCont compared with Minimum; and (2) performances of algorithms for bounded pattern matching using views, i.e., the effectiveness, efficiency and scalability of algorithms BMatch, BMatch\text{min}.

Experimental setting. We used the following data.

(1) Real-life graphs. We used four real-life graphs: (a) Amazon [3], a product co-purchasing network with 54.8K nodes and 1.78M edges. Each node has attributes such as title, group and sales-rank, and an edge from product \( x \) to \( y \) indicates that people who buy \( x \) also buy \( y \). (b) Citation [1], a collaboration network with 1.4M nodes and 3M edges, in which nodes represent papers with attributes such as title, authors, year and venue, and edges denote citations. (c) YouTube [4], a recommendation network with 1.6M nodes and 4.5M edges. Each node is a video with attributes such as category, age and rate, and each edge from \( x \) to \( y \) indicates that \( y \) is in the related list of \( x \).

(2) Synthetic graphs. We designed a generator to produce random graphs, controlled by the number \(|V|\) of nodes, the number \(|E|\) of edges, and an alphabet \(\Sigma\) for node labels. We enforced a set of access constraints during random generation.

(3) Pattern queries. We implemented a generator for pattern queries controlled by: the number \(|V_p|\) (resp. \(|E_p|\)) of pattern nodes (resp. edges), and node label \(f_v\) from an alphabet \(\Sigma\) of labels drawn from corresponding real-life graphs. We denote \((|V_p|, |E_p|)\) as the size of pattern queries, and generated a set of 30 pattern queries with size \((|V_p|, |E_p|)\) ranging from \((3,2)\) to \((8,16)\), for each data graph. We also produced a set of 100 synthetic pattern queries to constitute query workload, using label set \(\Sigma\), that is used for synthetic graph generation.

(4) Views. We generated views for Amazon following [21], designed views to search for papers and authors in computer science for Citation, and generated views for Youtube following [14]. For each of the real-life graphs, a set \(\mathcal{V}\) of 50 view definitions with different sizes e.g., \((2,1), (3,2), (4,3), (4,4)\) and structures are generated. For synthetic graphs, we randomly generated a set of 50 views whose node labels are drawn from a set \(\mathcal{S}\) of 10 labels and with sizes of \((2,1), (3,2), (4,3)\) and \((4,4)\). For each view set \(\mathcal{V}\), we force that \(Q \not\subseteq \mathcal{V}\), for each \(Q\) used for testing.

(5) Access schema. We investigated real-life graphs, and extracted an access schema \(C\) with a set of access constraints \(\varphi\) for each of them. A set of typical access constraints are shown in Fig. 6. For each access constraint \(\varphi = (Q, f_L, Q_R, N)\), we computed an index \(I_{\varphi}\) for it. Since \(N\) is no more than 100 for each chosen \(\varphi\), hence the space cost of an index \(I_{\varphi}\) ranges from a few megabytes to dozens of megabytes, for each \(\varphi\). In addition, the index \(I_{\varphi}\) is built upon a hashtable, with a distinct
We evaluate the efficiency of $Q_L$ as the key, and a set of matches $G_s$ of $Q_r$ as values. Thus, the fetch time on $I_r$ for any $G_L$ is very fast, and can be viewed as a constant. On synthetic graphs, we manually generated a set of access constraints and computed indexes for these access constraints, along the same line as performed on real-life graphs. As index construction is a one-off task and can be performed off-line, we do not report its computational time.

(6) Implementation. We implemented the following algorithms, all in Java: (1) JCont for determination of joint containment; (2) MCG [25] for finding maximally containing rewritings $Q_r$; (3) VF2 [10] for performing matching evaluation on $G$, BMatch for matching with $V(G)$ and $G_Q$; and (4) Minimum for identifying a pair $(\forall', C')$ from $\forall$ and $C$, and $\text{BMatch}_{min}$ which revises BMatch by using $(\forall', C')$ identified by Minimum.

All the tests were run on a machine with an Intel Core(TM) 2 Duo 3.00GHz CPU and 4GB memory, using Ubuntu. Each experiment was run 10 times and the average is reported.

Experimental results. We next present our findings.

Exp-1: Joint containment checking. We first evaluate the performance of JCont vs. Minimum.

Performance of JCont vs. Minimum. We evaluate the efficiency of JCont vs. Minimum. Fixing $\forall$ and $C$ for real-life graphs, we varied the pattern size from $(4, 4)$ to $(8, 16)$, where each size corresponds to a set of pattern queries with different structures and node labels. We find the following. (1) JCont and Minimum both are efficient, e.g., it takes JCont on average $145.5$ ms to decide whether a pattern with size $(8, 16)$ is jointly contained in $\forall$ and $C$. (2) Both two algorithms spend more time over larger patterns, which are consistent with their computational complexities. Due to space constraint, we do not report detailed figures here. (3) We compute a ratio $R_T = \frac{T_{\text{JCont}}}{T_{\text{Minimum}}}$, where $T_{\text{JCont}}$ and $T_{\text{Minimum}}$ are the time used by JCont and Minimum, respectively, to evaluate performance gap between JCont and Minimum. As shown in Fig. 7(a), JCont accounts for about $75.7\%$ of the time of Minimum, on average, since it takes Minimum more time to pick a $V_i$ from $\forall$ (resp. $\varphi_j$ from $C$).

To investigate the effectiveness of Minimum, we defined a ratio $R_S = \frac{S_a}{S_b}$, where $S_a = |\forall'(G)| + \sum_{\varphi_j \in C} N_j \cdot |Q_{\varphi_j}|$, $S_b = |\forall(G)| + \sum_{\varphi_j \in C} N_j \cdot |Q_{\varphi_j}|$, as the ratio of the total size of view extensions $\forall'(G)$ and $G_Q$ identified by Minimum to the total size of whole set of $\forall(G)$ and indexes in $C$. Fixing $\forall$ and $C$ over real-life graphs, we varied pattern size $(|V_p|, |E_p|)$ from $(4, 4)$ to $(8, 16)$ and evaluated the ratio $R_S$. As shown in Fig. 7(b), Minimum is effective, it finds a pair $(\forall', C')$ with total size $S_a$ substantially smaller than $S_b$, i.e., taking only about $25.2\%$ of $S_b$ for all real-life graphs, on average. As will be shown, using $(\forall', C')$ can substantially improve efficiency of matching computation.

Exp-2: Bounded pattern matching using views. We study the effectiveness, efficiency and
scalloplity of BMatch, BMatchmin, compared to VF2 [10] using real-life and synthetic graphs.

Effectiveness. We define following three metrics and evaluate effectiveness of bounded pattern matching using views with real-life graphs.

1. We defined a ratio $R_{ACC}$ as accuracy, to measure the result quality when access schema is absent, by following F-measure [28]. Here, $R_{ACC} = \frac{2 \cdot \text{recall} \cdot \text{precision}}{\text{recall} + \text{precision}}$, where recall = $\frac{|S|}{|S_m|}$, precision = $\frac{|S|}{|S|}$, $S_i$ consists of matches in $Q(G)$, $S_m$ is the set of matches in $Q_g(G)$, and $S$ consists of “true” matches that can be identified from $Q_g(G)$, where $Q_g$ refers to the maximally containing rewriting of $Q$ w.r.t. $V$.

2. We used $R_C = \frac{\sum_{\mathcal{C} \subseteq \mathcal{C}'} |Q_{\mathcal{C}}|}{|Q(G)|}$ to show the proportion of $|Q_{G}|$ in $|Q(G)|$. Here, $G_Q$ is constructed from $\mathcal{C}'$, which is a subset of $\mathcal{C}$ and takes a set of access constraints $\varphi_i$ that are used by BMatch when matching evaluation, and $|Q(G)|$ is the total size of matches of $Q$ in $G$.

3. We used $R_e = \frac{|E_{c}|}{|E_{p}|}$ to show how large a pattern query needs to be “covered” by access constraints.

Figures 7(c)-7(e) report three ratios on real-life graphs, which tell us the following. The ratio $R_{ACC}$ is, on average, 77.3%, 73.6%, and 76.8% on Amazon, Citation and Youtube, respectively. In the meanwhile, the average ratios of $R_C$ and $R_e$ reach 10.4% and 18.8%, 14% and 20.6%, 11.7% and 19.4% on Amazon, Citation and Youtube, respectively. These together show that access constraints often cover a small but critical part of pattern queries, e.g., 16.11% of total edges of $Q$ on average, and provide limited but key information, e.g., 10.89% of the size of match result to improve accuracy by more than 20%, on average.

Efficiency. Figures 7(f), 7(g) and 7(h) show the efficiency on Amazon, Citation and Youtube, respectively. The x-axis represents pattern size ($|V_p|$, $|E_p|$). The results tell us the following. (1) BMatch and BMatchmin substantially outperform VF2, taking only 9.5% and 3.8% of its running time on average over all real-life graphs. (2) All the algorithms spend more time on larger patterns.
Nonetheless, BMatch and BMatch$_{\text{min}}$ are less sensitive to the increase of $|Q|$ than VF2, as they reuse earlier computation cached in view extensions and hence save computational cost. (3) BMatch$_{\text{min}}$ is more efficient than BMatch, taking only 41.2% time on average over real-life graphs, as it uses smaller $\mathcal{V}(G)$ and $G_Q$.

**Scalability.** Using synthetic graphs, we evaluated the scalability of BMatch, BMatch$_{\text{min}}$ and VF2. Fixing $|Q| = (4, 6)$, we varied the node number $|V|$ of data graphs from 0.3M to 1M, in 0.1M increments, and set $|E| = 2|V|$. As shown in Fig. 7(i), BMatch$_{\text{min}}$ scales best with $|G|$ and is on average 1.4 and 22.1 times faster than BMatch and VF2, which is consistent with the complexity analysis, and the observations in Figures 7(f), 7(g) and 7(h).

**Summary.** We obtain the following findings through our experimental evaluation. (1) It is efficient to determine whether a pattern query can be *boundedly evaluable with views*. For a pattern query $Q$ with size $(8, 16)$, it only takes JCont 145.5 milliseconds to determine whether $Q \sqsubseteq \mathcal{J} [V, C]$. (2) *Bounded pattern matching using views* is effective in querying large social graphs. For example, by using $\mathcal{V}(G)$ and $G_Q$, pattern matching via subgraph isomorphism takes only 9.3% of the time needed for computing matches directly in YouTube, and 10.6% on synthetic graphs. Moreover, our optimization technique is effective, Minimum can reduce size of $\mathcal{V}(G)$ and $G_Q$ and improve BMatch by 143% on real-life graphs. Our matching algorithms also scale well with data size.

**6. Conclusion**

We have studied *bounded pattern matching using views*, for pattern queries defined in terms of subgraph isomorphism, from theory to algorithms. We have introduced access schema for graphs, proposed a notion of joint containment for characterizing bounded pattern matching using views, and provided an efficient algorithm for joint containment checking. Based on the characterization, we have developed an matching algorithm by using views and a size-bounded fraction, and moreover, we have also provided optimization strategy to improve efficiency of matching computation. Our experimental results have verified the effectiveness, efficiency and scalability of our algorithms, using real-life and synthetic data.

The study of bounded pattern matching using views is still in its infancy. One issue is the selection problem for views and access schema. Another problem concerns scale-independence for GPM.
